

Jennifer's Environment Diagram Cheat Sheet

Assignment statements:

```
x, y = 2, 3
```

```
x, y = y, x
```

(This swaps x and y: x becomes 3 and y becomes 2)

- 1) Evaluate operands on RHS (from left to right)
- 2) Bind variables on LHS to values on RHS

Call Expressions:

```
f(lambda: x)
```

(In this example, note that the lambda's parent is global!)

- 1) Evaluate operator
- 2) Evaluate operands (from left to right)
- 3) Apply the function to the arguments, opening a new frame

Opening a New Frame:

- 1) Frame number
- 2) Frame name
- 3) Frame's parent
- 4) Bind parameters to arguments
- 5) Start executing body of function

Frames Objects

def Statements:

- 1) On RHS: write “func”, function name (the intrinsic name), parameters, and parent frame (the frame in which that function is defined)
- 2) On LHS, bind function object to its name (the bound name)

When importing built-in functions like add, write “...” in place of the formal parameters.

Lambda Functions:

```
lambda x, y: x + y
```

Variables before colon are parameters; expression after colon is return value.

```
>>> lambda: 10                      >>> (lambda: 10)()
Function                                      10
```

Variable Lookup:

- Is variable in current frame?
 - If yes, return its value
 - If no, go to **parent** frame, and ask again (is variable in *this* frame?)
- Procedure repeats until we've found the variable or we hit the global frame. If we can't find the variable in the global frame, this will give an **Error**.

Things to pay attention to:

- Do not write or draw arrows to variables. Names can only be bound to values, not to variables!
- Distinguish between functions vs. call expressions. `f` is a function, while `f()` is a call expression.
- When you define a function, do not look into its body (everything that's indented). Only look inside a function after you have called it!
- The parent of a frame is where it was **defined**, *NOT* where it was called! This is where the `def` statement appeared, or where the lambda expression was evaluated.
- Remember to evaluate all the operators and operands before opening a new frame for that function.
 - `f(lambda: x)`
 - In this example, note that the lambda's parent is global!
- If a function doesn't have an explicit return statement (it doesn't explicitly say `return _____`), then the return value will be `None` implicitly.
- Once we reach a return statement, we immediately exit from that function and don't execute any of the code that appears afterwards.
- Do not open new frames for built-in functions like `add`, `sub`, `mul`, `max`, `min`, etc. We don't know these functions are implemented in Python (like how exactly the people who built Python decided to add 2 numbers) and thus can't trace through these functions in an environment diagram.
- **Sanity Checks:**
 - At the very end of your environment diagram, double check to make sure every frame except the global frame has a return value. (If not, something went wrong so backtrack!)
 - When we reach the return value for a frame, we're done with that frame, and we shouldn't be adding any more variable bindings within that frame.
